Abstract

Aims To investigate whether effects of the ASSIST school-based smoking prevention intervention diffused from students to the people they lived with.

Design Secondary analysis of a cluster randomized control trial (cRCT).

Setting England and Wales.

Participants 10,730 students aged 12-13 years in 59 schools assigned using stratified block randomisation to the control (29 schools, 5,372 students) or intervention (30 schools, 5,358 students) condition.

Intervention and comparator The ASSIST intervention involves 2-days of off-site training of influential students to encourage their peers not to smoke over a 10-week period. The control group continued with their usual education.

Measurements The outcomes were the proportion of students who self-reported living with a smoker, and the smoking status of each resident family member/caregiver. Follow-up assessments were immediately after the intervention and at 1- and 2-years post-intervention.

Findings The odds ratio for living with a smoker in the intervention compared to control group was 0.86 (95% confidence interval 0.72, 1.03) immediately after the intervention, 0.84 (0.72, 0.97) at a 1-year follow-up, and 0.86 (0.75, 0.99) at a 2-year follow-up. In a three-tier multilevel model with data from all three follow-ups, student-reported smoking by fathers (OR = 0.90, 95% CI 0.80, 1.00), brothers (OR = 0.78, 95% CI 0.67, 0.92), and sisters (OR = 0.80, 95% CI 0.69, 0.92) were lower in the intervention compared to control group. Sub-group analyses by baseline smoking status suggested these effects were more consistent with prevention of uptake than prompting cessation.

Conclusions The ASSIST intervention may have reduced the prevalence of smoking in people who lived with students. This indirect transmission is consistent with the predictions of diffusion of innovations theory which underpins the design of ASSIST. These findings are from exploratory analyses and require independent replication.

Introduction

A number of observational studies have found a concordance in smoking initiation, maintenance and cessation amongst peers.^{1, 2, 3} In the Framingham Heart Study, social network data collected over a 29-year period showed smoking cessation by a spouse decreased a person's chances of smoking by 67%, a sibling by 25%, and a friend by 36%.¹ There has, however, been less examination on whether intervention effects are transmitted. In the PROMoting School-community-university Partnerships to Enhance Resilience (PROSPER) study, friends of participants who received the Strengthening Families Program for Youth 10–14 (SFP) but were unexposed themselves were less likely to get drunk and use cigarettes at a three year follow-up if they had three or more friends attending the SFP compared with those with no friends attending the SFP.⁴ However, as neither receipt of SFP or friendships were randomly assigned, this association may reflect pre-existing differences in the social networks of families and students in risk factors for student drunkenness and cigarette use.

ASSIST is a school-based smoking prevention intervention, found to be effective in reducing the prevalence of weekly smoking in students aged 12-13 years.⁵ In ASSIST, influential students are identified and trained to diffuse non-smoking information and norms, principally through conversations with their friends. The intervention is delivered in many areas of the United Kingdom, with anecdotal reports from the team that trains ASSIST intervention delivery staff that students have conversations with their family about smoking, suggesting there may be a potential spill over effects. In the cluster randomised controlled trial (cRCT) of the ASSIST intervention, student reports on the smoking status of family/caregivers were collected, providing an unusual opportunity to explore whether intervention effects are diffused beyond the original intended group (students) to family members/caregivers. We conducted exploratory analysis to test the hypothesis that there will

be a reduced prevalence of smoking in the families/caregivers of students who attended an ASSIST intervention school compared to those in control schools. In sub-group analyses by families/caregivers baseline smoking status we explored potential effects on both smoking uptake and cessation.

Methods

Design

A Stop Smoking in Schools Trial (ASSIST) used a two-arm cRCT design and was conducted in schools in the west of England and southeast Wales. In 2001, 223 secondary schools were invited to participate. One hundred and twenty-seven schools expressed an interest, were visited, and 113 agreed to participate. Sixty-six schools were randomly sampled from these 113 with stratification by country, type of school (independent or state), mixed-sex or single-sex, English-speaking or Welsh-speaking, size (<200 or ≥ 200 students), and level of entitlement to free school meals (above or below the median entitlement of 19%). Of these 66 schools, 59 signed an agreement to be randomised. The Multi-Centre Research Ethics Committee for Wales reviewed the trial protocol and judged it as meeting ethically acceptable standards. The current analysis was not proposed in the study protocol and uses data gathered at baseline (Sept 2001–Feb 2002), immediately after the intervention (Jan 2002–May 2002), and at 1-year (Nov 2002–May 2003), and 2-year follow-up (Nov 2003–May 2004).⁷ The manuscript adheres to the CONSORT guidelines on the reporting of cluster randomised controlled trials (cRCTs).⁶

Procedures

Stratified-block randomisation was used with strata defined by the same criteria as random sampling. Written consent was obtained from parents on an opt-out basis and students provided written assent. Full details of the study design and data collection methods can be found elsewhere (ISRCTN 55572965).⁷

Intervention

ASSIST is an informal peer-led smoking prevention intervention based on diffusion of innovations theory (see Table S1 for a full description).⁸ It aims to diffuse and sustain non-smoking norms via secondary school students' social networks in UK Year 8 (aged 12-13). In intervention schools, 18.7% of students were trained to be peer supporters (range across schools was 14.8% to 24.6%).

Measures and outcomes

At baseline, students were asked to complete a questionnaire which included questions on their age, sex, the family affluence scale,⁹ and smoking behaviour. Students at 12 intervention and 12 control schools provided a saliva sample for cotinine analysis at 2-year follow-up, to minimise reporting bias.¹⁰ At baseline and each of the three post-intervention data collections students were also asked, "Does anyone who lives in your house smoke tobacco e.g. cigarettes, cigars or pipes? Please don't include yourself." This was coded into a binary variable of "any smoker" or not. Those who lived with a smoker were asked to write who the smokers were. Responses were coded into the outcomes of residence with a smoking: mother, father, brother, sister, grandmother, and grandfather. Preliminary analysis showed few students lived with other family members/caregiver who smoked. Only 1.9% had an aunt who smoked, 2.1% a smoking uncle, 1.3% boyfriend of a parent and 0.3% a girlfriend of a parent who smoked. Analysis was not conducted for these family members/caregivers, but

they were included in analysis of the “any smoker” group. Analyses were run for each of seven outcomes – student reported smoking of a mother, father, brother, sister, grandmother, grandfather and any smoker.

Statistical methods

Three multilevel logistic regression models (students nested within schools) were fitted with the outcome being smoking prevalence, separately for the three follow-up occasions: immediately after the intervention, at the 1-year and 2-year follow-up. As predictors, each of these models included the five school-level stratifying variables, the family affluence score, family car ownership and the respective family/caregivers' smoking behaviour at baseline. To allow individuals with missing measures at follow-ups to be included in the analysis, and reduce bias because of loss to follow-up,¹¹ we also carried out analyses with a three-level model using data from all follow-up periods together; schools were at level 3, students at level 2, and follow-up measurements at level 1. Model parameters were estimated with first-order penalised quasi-likelihood within MLwin (version 3.02) using the *runmlwin* command in Stata (version 15.0).

We conducted multiple sub-group analyses. To look at the effects of the intervention on uptake and cessation we conducted separate analyses according to family/caregivers' baseline smoking status. This analysis was repeated after imputing missing data as if the family members' unknown follow-up smoking status had not changed from its observed value at baseline. To test the hypothesis that effects may only occur in family/caregivers who lived with peer supporters (who are trained to diffuse and are therefore exposed to more non-smoking messages than non-peer supporter students), we re-ran analyses after excluding nominated peer supporters from the control and intervention condition. To examine whether smoking cessation in students explained any indirect effect of ASSIST, we re-ran analyses

after excluding students who smoked at baseline. As analyses were exploratory in nature, we did not adjust for multiple comparisons.¹² All analysis was by intention to treat.

Results

Figure S1 shows the trial profile. Two schools withdrew after randomisation and replaced by one from the same strata of interested schools. Of the 11,043 potentially eligible students in the 59 participating schools, 313 (3%) were withdrawn by their parents or carers before collection of data at baseline. Twenty students were excluded as they indicated that they did not live with a resident who smoked but then named a relative. At every data collection point more than 80% of eligible students provided information on whether the people they lived with smoked.

The proportion of students that lived with a smoker decreased from 54.2% (5,460 of 10,066) at baseline to 49.7% (4,531/9,123) at the 2-year follow-up. At baseline, mothers (31.7%) and fathers (30.9%) were most common family member to smoke in the household (Table 1). The proportion of students that lived with a smoker was lower in the intervention than control group at baseline (51.2% vs. 57.4%) and all three follow-up assessments (immediately after the intervention: 48.9% vs. 54.7%; 1-year: 48.4% vs 54.4%; 2-years: 46.7% vs. 52.8%). The odds ratio for living with a smoker in the intervention compared to control group was 0.86 (95% confidence interval 0.72, 1.03) immediately after the intervention, 0.84 (95% CI 0.72, 0.97) at 1-year follow-up, and 0.86 (95% CI 0.75, 0.99) at 2-year follow-up (Table 2). In the three-tier multilevel model, with data from all three follow-ups, the odds of students living with a smoking fathers (OR = 0.90, 95% CI 0.80, 1.00), brothers (OR = 0.78, 95% CI 0.67, 0.92), and sisters (OR = 0.80, 95% CI 0.69, 0.92) were lower in the intervention than control arm (Figure S1).

In sub-group analyses, the odds of smoking uptake was lower for fathers, brothers and sisters immediately after the intervention and the 1-year follow-up in the intervention than control arm (Table S2). There was little evidence of a beneficial effect on smoking cessation. Analysis into smoking uptake and cessation where missing data was imputed with baseline smoking status (Table S3), which removed peer supporters (Figure S2), or students who smoked at baseline from analyses (Figure S3), had little impact on estimates.

Discussion

These exploratory analyses suggest a school-based smoking prevention intervention may have reduced the prevalence of smoking in people who live with students. These residents did not directly receive the intervention. These analyses were not part of the original trial protocol. As such they require replication in an independent study before informing practise.

Comparison with existing studies

The transmission of smoking behaviours to siblings we found replicates the results from the social network analysis in the Framingham study,¹ and the indirect effect of the SFP family-based substance use prevention program on cigarette use in friends of participants.⁴ Our analysis has extended the results from these studies by finding evidence of diffusion of an intervention effect from adolescents to family members not directly exposed. Importantly, as ASSIST was a randomised controlled trial, the potential for a confounding effect of participant selection into an intervention and individual and network-level differences in risk factors for smoking status, was minimised. Although we are aware of diffusion of intervention effects in RCTs evaluating weight loss¹³ and bariatric surgery,¹⁴ to our knowledge this is first evidence of diffusion of an intervention effect to smoking behaviour,

and from adolescent to a parent. The transmission of effects is consistent with the predictions of diffusion of innovations theory⁸ on which ASSIST is based.

Among the candidate mechanisms explaining a beneficial effect of ASSIST on family/caregivers, one hypothesis consistent with the associations observed in the Framingham study is that ASSIST prompted smoking cessation in students, which in turn influenced family/caregivers smoking status.¹ A sub-group analysis excluding students who smoked produced estimates comparable to the main results. This suggests students did not need to stop smoking to influence other family/caregivers smoking status. Another explanation is that peer supporters carried on their role of passing on messages informally to encourage non-smoking at home. The sub-group analysis according to baseline family member smoking status suggests that the effect of the intervention on smoking prevalence was more consistent with preventing uptake than promoting cessation. That effects remained similar for all outcomes when peer supporters were excluded from analysis, suggests that the spill over effects of the ASSIST intervention to those who lived with students occurred across the whole year group not just amongst the families of peer supporters.

Strengths and weaknesses

The strengths of this study are that it is the first to examine the indirect effect of a school-based intervention to parents, siblings and grandparents. There was some differential loss to follow-up in the original sample according to student smoking behaviour and family affluence. The adjustment for these variables would have acted to minimise any bias introduced by differential loss to follow-up, assuming drop-out at random, and would not have explained the effects we observed. There were imbalances in the proportion of residents who smoked between arms at baseline. As all analyses adjusted for the baseline smoking status of resident(s), these imbalances do not preclude valid inferences being drawn about the

intervention effect.¹⁵ Outcomes were all self-reported and there could be differential reporting bias between intervention and control arms.¹⁶ However, as described elsewhere, no difference was found in ASSIST between students who self-reported not smoking and had a salivary cotinine concentration greater than 15 ng/mL between groups, suggesting any bias in student self-reported smoking was balanced.⁵ The motivation for conducting these analyses emerged from feedback from the ASSIST implementation team and was hypothesis driven; however, interpretation should be cautious since they were not pre-registered and require independent confirmatory studies ideally with more recent data than these data gathered in 2001-2004.

Conclusions

Our findings suggest a school-based smoking prevention intervention may have reduced smoking amongst non-participating family members/caregivers. If these findings are replicated, it would suggest outcomes targeted by an intervention should be collected on those who might be indirectly exposed (e.g. spouses, family members, siblings, friends, co-workers) to gain a more comprehensive account of potential benefits. It also suggests greater attention should be paid to network-level processes which might facilitate diffusion of effects in intervention design.
